Abstract.—A new sinistrally coiled univalved mollusk *Catalanispira* n. gen. is described with two species; *Catalanispira reinwaldti* (Öpik, 1930) from the Middle Ordovician Kõgekallas Formation (Darriwilian) of Estonia and *Catalanispira plattevilensis* n. gen. n. sp. from the Upper Ordovician Platteville Formation (Sandbian) of northern Illinois, USA. Morphological features include a large, low-trochiform shell, a narrow lenticular aperture, a deep funnel-like umbilicus, a falcate inner lip and a large (1.4 mm wide) protoconch. Ornamentation consists of fine commarginal growth lines or ribs but superimposed on a slightly irregular shell surface. *Catalanispira* n. gen. is placed within the sinistrally coiled order Mimospirida and the family Onychochilidae, and Catalanispirinae n. subfam. is proposed. The large Lower Ordovician (Tremadocian) *Pelecogyra* Ebbestad and Lefebvre, 2015 from Morocco and France is transferred to this new subfamily. The well-preserved initial growth stage of *Catalanispira plattevilensis* n. gen. n. sp. is cap-shaped, slightly asymmetrical, unusually large, and smooth, and represents either an unusually large embryonic shell (protoconch 1) or a larval shell (protoconch 2). It differs from the smaller protoconch described for the clisospirine *Mimospira* Koken in Koken and Perner, 1925, which might include a multiwhorled larval shell (protoconch 2). Mimospirids are dominantly Ordovician, and have been classified as untorted mollusks (only distantly related to gastropods), dextral hyperstrophic gastropods, or sinistral orthostrophic gastropods. Sinistral asymmetry already in the embryonic shell and lack of conclusive evidence for coiling direction, e.g., an operculum, could suggest that *Catalanispira* n. gen. or similar mimospirids were sinistral orthostrophic gastropods. Currently the group is therefore classified as a group of sinistral orthostrophic gastropods, unranked within the Gastropoda.

Introduction

Gastropods or gastropod-like mollusks with a sinistrally coiled (left-handed) shell are a small but conspicuous part of Ordovician benthic associations. Whereas modern gastropod shells are overwhelmingly dextrally coiled (right-handed), and sinistral morphs or populations with such shells are rare (Vermeji, 1975; Robertson, 1993; Schilthuizen and Davidson, 2005), a number of lower Paleozoic groups have only sinistrally coiled shells (Knight et al., 1960; Bandel, 1993; Ebbestad and Lefebvre, 2015). Most are considered gastropods, defined as mollusks distinguished by the early developmental process of torsion in which all organs of the mantle cavity are twisted (torted) through 180° relative to the head and foot of the animal.

After torsion, the morphologically right side (originally posterior) becomes the topographically left side (and vice versa) when viewed from above, and the mantle cavity lies in an anterior position over the head. Torsion produces marked asymmetry or reduction of the soft parts of the mantle cavity in many groups. In most gastropods, torsion is counterclockwise, which leaves the organs originally on the morphological right side largely intact, forming an anatomically dextral animal.

In most cases, the anatomically dextral gastropods have dextrally coiled shells, whereas their anatomical mirror images (gastropods that are anatomically sinistral and have undergone clockwise torsion) have a sinistrally coiled shell. These ‘true’ sinistral gastropods are termed sinistral orthostrophic whereas those with a ‘regular’ dextral shell are termed dextral orthostrophic (Fig. 1).

A different arrangement occurs when the soft organs of a snail are morphologically dextral, but the shell coils sinistrally, a condition called dextral hyperstrophy. The opposite is sinistral hyperstrophy (sinistrally arranged organs, dextrally coiled shell; see Peel and Horný, 1996 for a rare fossil example). To show this condition, hyperstrophic shells are illustrated with the apex down (Knight, 1952). This places the aperture on the same side as in a corresponding orthostrophic form, which is typically illustrated with the apex up, the axis of coiling vertical, and the aperture facing the viewer. In effect, the hyperstrophic shell can be seen as coiling up the axis of coiling, rather than down as in an orthostrophic form (Fig. 1).

This condition is rare in Recent adult gastropods, although larval hyperstrophy (heterostrophy) can be widespread (Robertson, 1993). Heterostrophy occurs when coiling direction reverses at

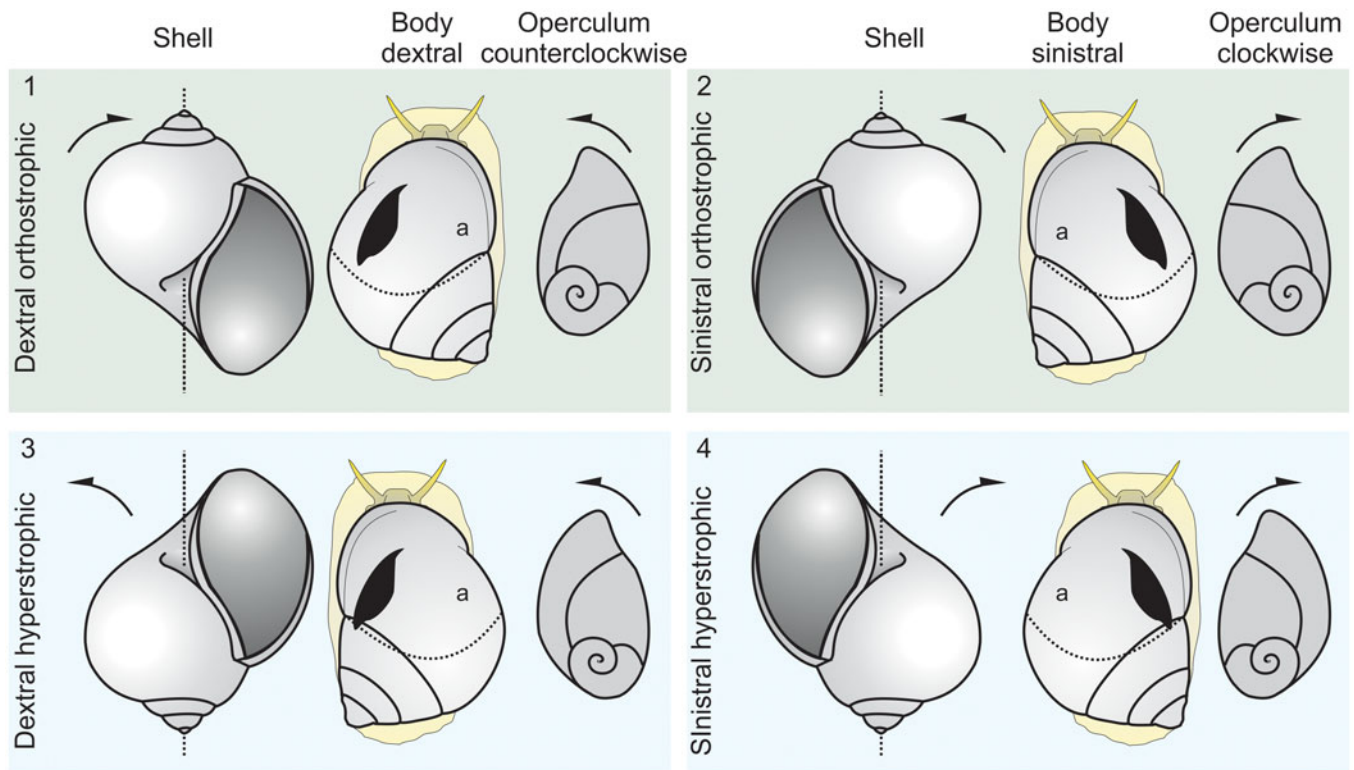

Figure 1. The relationships of shell coiling, internal anatomy, and coiling of the operculum: (1) dextral orthostrophy; (2) sinistral orthostrophy; (3) dextral hyperstrophy; (4) sinistral hyperstrophy. First column of each figure: stippled vertical line = axis of coiling; curved arrow = coiling direction of shell when oriented with spire up and aperture facing the viewer. Second column in each figure: stippled curved line = the anterior mantle cavity; black silhouette = single ctenidium (to illustrate post-torsional asymmetry); a = anus. Third column in each figure: curved arrow = coiling direction; operculum oriented with outside facing viewer and positioned as it would appear when shell is oriented with spire up.

the transition between the larval and adult shell. A dextral orthostrophic shell can be derived from a sinistrally coiled protoconch in which the anatomy remains dextral (dextral hyperstrophic; Robertson, 1993). Among the large group of heterobranch gastropods (Carboniferous–Recent), larval heterostrophy is a synapomorphic trait (Haszprunar, 1984). Heterostrophy occurs in some fossil lineages in the earliest teleoconch rather than at the transition from the larval shell. The coiling axis of the two stages can either be parallel (coaxial) or not (non-coaxial), with the oldest example of the latter occurring in the Devonian (Frýda and Ferrová, 2011). Frýda and Rohr (2006) showed coaxial heterostrophy in the Ordovician *Macluritoidea* Carpenter, 1861, whereas both coaxial and noncoaxial heterostrophy are documented in the Silurian–Cretaceous *Porcelloidea* Koken in Zittel, 1895 (Bandel, 1993; Frýda, 1997; Frýda and Ferrová, 2011; Frýda et al., 2019).

The Ordovician *Maclurites* Le Sueur, 1818 and its allies are dextral hyperstrophic; the aperture would appear to be to the left if the shell is oriented in the typical manner with the apex upward, but if the aperture is placed to the right, the shell coils naturally upward with the apex forming the functional base of the shell as a direct consequence of the mode of life. The interpretive limitation is that the inferred hyperstrophy of shells such as *Maclurites* is not evident from external appearance alone. In fossil material, it is often difficult to establish whether gastropods with a sinistrally coiled shell were sinistral orthostrophic or dextral hyperstrophic unless an operculum is

associated. This is because the coiling direction of the operculum, when spiral and viewed exteriorly, is always opposite to the true coiling direction of the shell, i.e., counterclockwise if the conch is dextral and clockwise if the conch is sinistral. Indirectly, this reveals the morphological arrangement of the soft parts, because this is opposite to the coiling direction of the operculum. Yochelson (1984) discussed the limitations of inferring anatomy of soft parts relative to shell coiling, because a hyperstrophically coiled shell must not automatically be assumed to have hyperstrophic soft parts. The sinistral coiling of the *Maclurites* operculum, combined with the seemingly sinistrally coiled shell, demonstrates that the condition in this snail was dextral hyperstrophic. It should be noted that Frýda and Rohr (2006) showed a heterostrophic condition in the Lower Ordovician macluritid *Macluritella stantoni* Kirk, 1927, with initial whorls coiling dextrally (suggesting dextral orthostrophy), and later whorls coiling sinistrally. The macluritoids thus might have had a dextral orthostrophic ancestor, with dextral hyperstrophy as a derived condition (Frýda and Rohr, 2006).

In Devonian *Tychobrahea* Peel and Horný, 1996, the conspiral shell appears to coil dextrally in a regular dextral orthostrophic way, but because the operculum also coils dextrally (clockwise), the condition was interpreted as sinistral hyperstrophic (Peel and Horný, 1996). When placed with the apex down, the shell coils sinistrally up the axis of coiling and the snail itself was presumably morphologically sinistral.

Figure 1 illustrates the relationships between the orthostrophic and hyperstrophic conditions described above. Other diagrams of the various morphological orientations and combination discussed herein were discussed by Knight (1952), Peel (1986), Robertson (1993), Peel and Horný (1996), Frýda and Rohr (2006), and Frýda (2012).

In the present study, *Catalanispira* n. gen., with the species *Catalanispira reinwaldti* (Öpik, 1930) and *Catalanispira plattevilleensis* n. gen. n. sp., is described from the Middle and Upper Ordovician (Darrivilian and Sandbian) of northern Estonia and eastern United States, respectively. It is sinistrally coiled and placed within Catalanispirinae n. subfam. of the family Onychochilidae Koken in Koken and Perner, 1925 of the order Mimospirida Dzik, 1983. These univalved mollusks comprise a group of entirely sinistrally coiled taxa known from the Cambrian–Devonian (Frýda, 2012), possibly extending into the Carboniferous (see Bandel, 2002, p. 47). However, their record is strongly biased toward the Ordovician where they constitute ~3% of known Ordovician gastropod and gastropod-like taxa (Frýda and Rohr, 1999, 2004; Frýda, 2012; Ebbestad et al., 2013; Ebbestad and Lefebvre, 2015). Mimospirids have variably been classified as untorted mollusks in the class Paragastropoda (Linsley and Kier, 1984), only distantly related to gastropods (Wagner, 2002), as dextral hyperstrophic gastropods (Knight et al., 1960 [pars.]; Horný, 1964 [pars.]; Wängberg-Eriksson, 1979; Peel, 1986), or as sinistral orthostrophic gastropods (Knight et al., 1960 [pars.]; Horný, 1964 [pars.]; Dzik, 1983, 1999; Frýda, 1999, 2001, 2012; Frýda and Rohr, 2004, 2006; Frýda et al., 2008). Current classifications regard them as basal gastropods of uncertain systematic position (Bouchet et al., 2005, 2017).

In addition to increasing the diversity of onychochilid mollusks, the new genus clarifies details of the early ontogeny and teleoconch morphology and partly elucidates relationships between onychochilids. Protoconch development in the group, previously only known from a few taxa, is described for *Catalanispira plattevilleensis* n. gen. n. sp.

Geological setting

During the late Middle and early Late Ordovician, both Laurentia and Baltica occupied equatorial warm waters in a broadly carbonate-dominated depositional regime (Torsvik and Cocks, 2017). Increased faunal exchange is evident, although both areas maintain their faunal integrity reflected in the recognition of different faunal provinces defined mainly on shared endemic brachiopod taxa (Harper et al., 2013). Laurentia in the west and Australia in the east, and areas in between, belonged to a broad east-west equatorial low-latitude province, whereas Baltica was part of the Anglo-Welsh Baltic province, together with Avalonia and North and South China.

Upper Ordovician geology and stratigraphy, eastern United States.—The Platteville Formation is part of a vast Upper Ordovician carbonate platform extending across midcontinent North America (Kolata et al., 1996). The formation consists largely of fossiliferous lime mudstone and wackestone, locally dolomitized, and exposed in outcrops in northern Illinois, eastern and southwestern Wisconsin, northeastern Iowa, and

southeastern Minnesota. Within the outcrop belt, it ranges in thickness from 6 to 42 m. Based on conodont biostratigraphy, the Platteville Formation lies entirely within the *Phragmodus undatus* Biozone (Sweet, 1984, 1987; Leslie, 2000; Leslie and Bergström, 2005). Regional correlations based on chemical fingerprinting of K-bentonite beds and tracing on gamma ray logs show that the Platteville Formation lies below the Millbrig K-bentonite Bed throughout its extent (Kolata et al., 1986, 1987, 1996, 1998). The Millbrig K-bentonite is a confirmed Ordovician Global Boundary Stratotype Section and Point (GSSP) marking the boundary between the Turinian and Chatfieldian stages of North America (Bergstrom et al., 2009) and has been dated to 452.86 ± 0.29 Ma (Sell et al., 2013). These stratigraphic relations support assignment of the Platteville Formation to the North American Turinian Stage of the Mohawkian Series and the global Sandbian Stage of the Upper Ordovician Series.

Near Dixon, in northern Illinois, five members are recognized within the Platteville Formation, including, in ascending order, the Pecatonica, Mifflin, Grand Detour, Nachusa, and Quimbys Mill. In this region, the formation has a consistent thickness of ~40 m and is well exposed in numerous open pit mines on the northern side of Dixon, most of which were developed by a succession of cement manufacturers over the last 150 years. There, the Mifflin Member consists of 5.5 m of thin, wavy, nodular beds containing a diverse, abundant, and well-preserved invertebrate fauna. Particularly notable are several localized pockets of unconsolidated marl formed by diagenetic alteration of the limestone. Fossils in these deposits tend to weather free of matrix. Nine well-preserved specimens of *Catalanispira plattevilleensis* n. gen. n. sp. were recovered from the marl deposits for this study.

Upper Middle and lower Upper Ordovician geology and stratigraphy: Baltoscandia.—The upper Middle and lower Upper Ordovician of Baltoscandia is characterized by distinct facies zones from west to east, with deeper water facies in the western, southwestern, and southern parts and a shallower carbonate platform to the north and northeast (Jaanusson, 1973, 1995; Harris et al., 2004; Meidla et al., 2014) (Fig. 2).

In the central part of Baltoscandia, argillaceous limestones of the Furudal and Dalby limestones occur at the Darrivilian-Sandbian transition, with a total thickness of ~30 m (Ebbestad and Högström, 2007; Bergström et al., 2011). The top of the Dalby Formation is marked by the Kinnekulle K-bentonite, recently dated to 454.06 ± 0.43 Ma (Ballo et al., 2019). The Kinnekulle and Millbrig K-bentonites have been considered coeval (Huff et al., 2010; Huff, 2016) but recent dating suggests that the former is older (Sell et al., 2013; Bauert et al., 2014; Ballo et al., 2019; Oruche et al., 2019).

Conodonts of the *Baltoniodus alobatus* Subzone of the *Amorphognathus tvaerensis* Biozone extend close to the Kinnekulle K-bentonite, which also marks the base of the Keila regional stage (Bergström et al., 2011). The Dalby Formation contains a rich and diverse fauna (see references by Ebbestad and Högström, 2007) and *Laeogyra reinwaldti* (Öpik, 1930) was reported from the Dalby Limestone in Dalarna by Frisk and Ebbestad (2007). The unit is well-constrained biostratigraphically, encompassing the Kukruse and Haljala regional stages, with the

Figure 2. Maps and stratigraphy: (1) Estonia with Scandinavia as inset; (2) USA with position of Illinois; (3) state of Illinois with location of Dixon county (box); (4) correlation between the late Middle–Upper Ordovician of Estonia and the Upper Ordovician of northern Illinois. Note that the scales for Estonia and Illinois are the same. See text for references to the stratigraphy. *An.*, *Angochitina* (Subzone); *Amorph.*, *Amporphognathus*; *Ar.*, *Armoricochitina* (Subzone); *B.*, *Baltoniodus*; *Belod. comp.*, *Belodina compressa*; *Chattf.*, *Chatfieldian*; *Kat.*, *Katian*; *L.*, *Laufeldochitina*; *Lag.*, *Lagenochitina* (Subzone); *Las.*, *Lasnamägi*; *Sz.*, *Subzone*; *Z.*, *Zone*.

base of the *A. tvaerensis* Zone appearing close to the base of the Dalby Limestone (Bergström, 2007). Although the conodont species is not confidently identified in Sweden, but found in Estonia, the base of the *Amorphognathus inaequalis* Biozone was taken to be at the base of the Dalby Limestone (Bergström, 2007; Bergström et al., 2011). Formerly, it was used as a subzone of the *Pygodus anserinus* Biozone, but Viira (2008) proposed to elevate it to biozone level.

Toward the east, shelf carbonates dominate the Estonian shelf area (northern Estonian facies belt), with contemporary strata to the Swedish Furudal and Dalby limestones being represented by the Kõrgekallas and Viivikonna formations (Uhaku and Kukruse regional stages, respectively). The latter unit is composed of argillaceous limestones with intercalations of the kukersite oil shale, and it holds the most diverse faunal assemblages in the Ordovician succession in Estonia (Hints, 1997). Öpik (1930) erroneously reported *Clisospira reinwaltdi* Öpik, 1930 from this unit. It is only 3 m thick in the northwestern outcrop area and ~20 m thick in the northeastern area, but it has wide regional extent and forms the so-called Baltic Oil Shale Basin (Bauert and Kattai, 1997) (Fig. 2).

The lower boundary of the Viivikonna Formation is very close to the Darrwilian–Sandbian boundary, identified by chitinozoans of the *Eisenackitina rhenana* Subzone and conodonts of the *A. inaequalis* Zone. The uppermost part lies within the *Baltoniodus gerdae* Subzone and the lower range of the *Diplograptus foliaceus* Biozone, although the upper part is missing in northeastern Estonia (Hints, 1997; Nölvak et al., 2006; Viira, 2008; Hints et al., 2010). The Kõrgekallas Formation is a thin-bedded argillaceous limestone unit in the upper part of the Uhaku Stage. It is only ~2 m thick in the northwestern outcrop area and ~18 m thick in the northeastern part (Hints, 1997). Within the Baltic Oil Shale Basin, the upper beds (Pärtlioru Member) contain the oldest kukersite in Estonia. Except for its lowermost part, the formation falls within the *P. anserinus* conodont Zone and the *Conochitina tuberculata* chitinozoan Biozone (Hints, 1997; Nölvak et al., 2006; Viira, 2008).

Locality information.—Specimens of *Catalanispira plattevellensis* n. gen. n. sp. were collected at two sites near Dixon, Illinois: Dixon site 1, a reclaimed quarry 2.0 km north of the intersection of White Oak Lane and Illinois State Route 2 (41°52'29.40"N, 89°27'2.34"W); Dixon site 2, an

abandoned quarry 2.60 km north of the intersection of White Oak Lane and Illinois State Route 2 (41°53'40.41"N, 89°26'56.0"W). The single specimen of *Catalanispira reinwaltdi* came from a now-vanished quarry at the southern lighthouse near Tallinn, Estonia. See Figure 2 for further details.

The Mimospirida, with emphasis on the Onychochilidae

Classification.—Ebbestad and Lefebvre (2015) discussed the current and reduced concept of Paragastropoda, with the order Hyperstrophina of Linsley and Kier (1984) encompassing only the Clisospiridae Miller, 1889 and Onychochilidae Koken in Koken and Perner, 1925. It was pointed out that it corresponds to the Mimospirina of Dzik (1983), making Hyperstrophina a junior objective synonym. Ebbestad and Lefebvre (2015) proposed to elevate the suborder Mimospirina to order Mimospirida. Bouchet et al. (2005, 2017) correctly assigned the two families to the superfamily Clisospiroidea, which is a senior objective synonym of the Onychochiloidea as introduced by Linsley and Kier (1984). Bouchet et al. (2005, 2017) also equaled the superfamily to the suborder Mimospirina, but because these are of different ranks, the placement of the superfamily in the order Mimospirida, as suggested by Ebbestad and Lefebvre (2015), is followed here. Frýda and Bouchet in Bouchet et al. (2005), Frýda (2012), and Bouchet et al. (2017) classified the Clisospiroidea as basal gastropods of uncertain systematic position, instead of the (paraphyletic) class Paragastropoda as proposed by Linsley and Kier (1984) (Table 1). It has been argued that the sinistral asymmetry of the embryonic protoconch 1 shows that they could not be hyperstrophic (Dzik, 1983, 1999), implying sinistral orthostrophy, and that other compelling evidence, e.g., an operculum, to demonstrate this condition is lacking (Frýda, 1995, 2012; Frýda and Blodgett, 2001; Frýda and Rohr, 2004, 2006; Frýda et al., 2008).

The Clisospiroidea, as proposed by Bouchet et al. (2005, 2017), is largely a summary of the proposals by Knight et al. (1960) and Horný (1964) (see Table 1). Knight et al. (1960) placed the subfamilies Clisospirinae and Progalerinae Knight, 1956 in the family Clisospiridae of the superfamily Clisospiroidea (as Clisospiracea), and the subfamilies Onychochilinae and Scaevogyrinae Wenz, 1938 within the family Onychochilidae in the superfamily Macluritoidea (as Macluritacea). Like Wenz (1938), Knight et al. (1960) did not recognize similarities between the two families, but Horný (1964) found that the Onychochilidae and the Clisospiridae were closely related sinistral and hyperstrophic gastropods. He added Atracurinae Horný, 1964 and Trochoclisinae Horný, 1964 to the Clisospiridae, and Hyperstropheminae Horný, 1964 to the Onychochilidae.

Dzik (1983) proposed to unite the two families in the suborder Mimospirina, without superfamily rank, and remarked that further subdivisions into subfamilies seemed difficult. Linsley and Kier (1984) maintained the family structure for the Clisospiridae but did not provide subfamilies for the Onychochilidae (Table 1). They united these two in the superfamily Onychochiloidea (as Onychochilacea), although the previously named Clisospiroidea would have priority, in their new order

Hyperstrophina of the class Paragastropoda. Previous classification of the group by Knight et al. (1960) within the Macluritoidea was contested by Dzik (1983) and later firmly refuted by Frýda and Rohr (2006); see also discussion by Morris (1991) and Wagner (2001, 2002).

Webers et al. (1992) proposed to return the largely Cambrian Scaevogyridae to family rank (subfamily by Knight et al., 1960; Bouchet et al., 2005, 2017) and that Onychochilidae could be an incertae sedis form taxon for Ordovician and younger sinistral forms of uncertain relationship.

Composition of the Onychochilidae.—The currently recognized subfamilies within the Onychochilidae are the Onychochilinae Koken in Koken and Perner, 1925, the Scaevogyrinae Wenz, 1938, and the Hyperstropheminae Horný, 1964. The last contains only the tiny Devonian *Hyperstrophema devonicans* Horný, 1964, known from only two specimens.

Ebbestad and Lefebvre (2015) included 14 Cambrian (Furongian) to Devonian genera in the Onychochilidae, without assignment to subfamilies. *Pervertina* Horný, 1964, known from two Upper Ordovician specimens (one in Sweden and one in the Czech Republic), was erroneously included in lieu of *Antispira* Perner, 1903, acknowledged by the authors as a junior synonym of *Antispira* following Frýda and Rohr (1999).

Wenz (1938) included only the Silurian *Onychochilus* Lindström, 1884 in the Onychochilidae, moving the three other genera originally included in the family by Koken and Perner (1925) to other families: *Mimospira* Koken in Koken and Perner, 1925 to the Clisospiridae and *Laeogyra* Perner, 1903 and *Helicotis* Koken in Koken and Perner, 1925 to his new family Scaevogyridae. There, he also placed *Scaevogyra* Whitfield, 1878, *Versispira* Perner, 1903 (as a subgenus of *Scaevogyra*), *Antispira* (tentatively), *Matherella* Walcott, 1912, *Matherellina* Kobayashi, 1933, and (tentatively) *Palaeopupa* Foerste, 1893, the last two as subgenera of *Matherella*. Subsequently, *Palaeopupa* was regarded an objective synonym of *Onychochilus* by Knight et al. (1960).

The families of Wenz (1938) were significantly revised by Knight et al. (1960) in the 'Treatise on Invertebrate Paleontology.' In a preamble to the Treatise work, Knight (1952, p. 2) regarded many of the families and subfamilies of Wenz as polyphyletic, although the reconstructed relationships in the Treatise might not have been much of an improvement. Scaevogyridae Wenz, 1938 was included as a subfamily in the Onychochilidae, with *Kobayashiella* Endo, 1937 added. *Laeogyra*, *Matherella*, and *Matherellina* were placed with *Onychochilus* in the subfamily Onychochilinae, also adding the Devonian *Sinistracirsa* Cossmann, 1908. Wängberg-Eriksson (1979) later added her new genera *Bodospira* Wängberg-Eriksson, 1979, *Angulospira* Wängberg-Eriksson, 1979, and *Tapinogyra* Wängberg-Eriksson, 1979 from the Boda Limestone (Upper Ordovician) of central Sweden, but at family level only. A further inclusion was the Devonian *Voskopiella* Frýda, 1992.

Webers et al. (1992) resurrected Scaevogyridae with a composition closer to that of Wenz (1938), including *Scaevogyra*, *Matherella*, *Matherellina*, and *Kobayashiella*. The poorly known, and possibly synonymous, genera *Versispira* and *Antispira* from the Ordovician of the Prague Basin were left unranked.

Table 1. Various classification schemes of taxa in the Clisospirioidea. The Devonian (D) Progalerinae was not discussed by Horný (1964) who only looked at the lower Paleozoic taxa; subsequently, Progalerinae was considered a junior synonym of Clisospirinae (Bouchet et al., 2005). Only modern family and subfamily endings are used here.

The widely differing opinions on the construction and composition of the Clisospirioidea mostly reflect our still very limited knowledge of most members of the group, and lack of details (e.g., the protoconch) or even clues to the question of hyperstrophy. Although it therefore seems prudent now to avoid major revisions of subfamilies, a new subfamily is introduced in the present study. This is justified by apomorphies in the protoconch and teleoconch that are not compatible with placement in any of the currently recognized subfamilies (see Systematic paleontology).

Distribution of onychochilids.—Frýda and Rohr (1999) presented the paleobiogeography of Ordovician Clisospiridae and Onychochilidae and discussed most of the taxa known at that time. Ebbestad and Lefebvre (2015) gave the distribution of 41 Cambrian (Furongian) and Ordovician onychochilid species when describing the new genus *Pelecogyra* Ebbestad and Lefebvre, 2015 from Morocco, the first onychochilid taxon identified from the Mediterranean margin of Gondwana. Recently the genus has also been identified in the Ordovician of Montagne Noire, France (Ebbestad et al., in press), which,

together with a record of *Mimospira* by Sdzuy et al. (2001) from Frankenwald in Germany, represents the only records of the group in the Armorican terrane. An unidentified onychochilid was identified by Rohr et al. (2001) in Ordovician strata of the Precordillera of South America, representing the Proto-Andean margin of Gondwana, and Dzik (2020) firmly identified clisospirid taxa in the Ordovician of Argentina.

The record of onychochilids and clisospirids is strongly biased toward the Ordovician (Frýda and Rohr, 1999; Ebbestad et al., 2013; Ebbestad and Lefebvre, 2015), but during the latest Cambrian (Furongian), several onychochilid genera were already widespread in Antarctica, North China, and eastern North America (Ebbestad and Lefebvre, 2015, fig. 6), with older occurrences of *Kobayashiella?* in the Miaolingian of Australia (Smith et al., 2019). Already in the Lower Ordovician and onward, they become rare in these areas. Instead, clisospirid and onychochilid taxa are widespread from the Dapingian onward in Perunica (Prague Basin) and Baltica (Baltoscandia), with particularly the Katian Boda Limestone representing a hot spot (Frýda and Rohr, 1999; Ebbestad et al., 2013; Ebbestad and Lefebvre, 2015).

Clisospirid generic diversity was low in the Early to Middle Ordovician, increasing markedly from the Darrivilian onward until an abrupt extinction phase at the end of the Ordovician (Frýda and Rohr, 2004; Frýda, 2012; Ebbestad et al., 2013). *Clisospira* and *Mimospira* survived into the Silurian (Peel, 1975, 1986; Wängberg-Eriksson, 1979), with new taxa emerging, e.g., *Angulospira*, *Conclisa* Horný, 1964, and *Onychochilus*. Occurrences in Perunica and Baltica still prevailed, but with a few taxa also found in eastern North America and North Greenland. Six Devonian taxa are attributed to the clisospirids (asterisks mark members of the Onychochilidae), all from central Europe (Czech Republic and one from Germany): *Antigyra* Horný, 1964, *Atracura* Horný, 1964, **Hyperstrophema* Horný, 1964, **Sinistracirsa*, **Sinistriconcha* Heidelberger and Bandel, 1999, *Trochoclis* Horný, 1964, and **Voskopliella*. A single species of **Onychochilus* was reported by Yoo (1988) from the Lower Carboniferous of Australia, and later moved to *Sinistriconcha* by Bandel (2002).

Figure 3. *Catalanispira plattevilensis* n. gen. n. sp., PRI 76976 (cross section), from base of Mifflin Member, Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2), northern Illinois, eastern USA. Shaded area = whorls filled with recrystallized calcite. Arrow points at base of whorl.

Material and methods

Nine specimens of *Catalanispira plattevillensis* n. gen. n. sp. from the upper midwestern United States and one specimen of *Catalanispira reinwaldti* from northern Estonia were available for this study. The specimens assigned to *Laeogyra reinwaldti* by Frisk and Ebbestad (2007) from the Dalby Limestone of central Sweden are not conspecific with *Catalanispira reinwaldti* and are here tentatively assigned to *Laeogyra* sp. All specimens were largely free from the matrix and only minor cleaning and development of the umbilical areas were necessary. Specimen PRI 76976 of *Catalanispira plattevillensis* n. gen. n. sp. was sectioned to provide a median transverse cross section of the whorls (Fig. 3). The rate of whorl expansion (W) is based on Raup (1966) and calculated by dividing the width:length ratio of two consecutive whorls. The resulting cross section was photographed under ethanol and a drawing was traced from this to prepare a figure. The base of the single specimen of *Catalanispira reinwaldti* was obscured by matrix and was mechanically prepared to reveal the umbilical side and part of the aperture. All specimens were coated with ammonium chloride prior to photography. Taxonomy follows Frýda and Bouchet in Bouchet et al. (2005). The descriptive term ‘apical cap’ is taken from Warén and Gofas (1996).

Repositories and institutional abbreviations.—Specimens of *Catalanispira plattevillensis* n. gen. n. sp. are deposited in the collections of the Paleontological Research Institution of Ithaca, New York, USA (PRI 76973–76977, Dixon site 1) and the University of Illinois Paleontological Collections, USA (ISGS 1017–1020, Dixon site 2). *Catalanispira reinwaldti* is deposited in the Natural History Museum, University of Tartu, Estonia (TUG 1053-13).

Systematic paleontology

Order Mimospirida Dzik, 1983

Family Onychochilidae Koken in Koken and Perner, 1925

Subfamily Catalanispirinae new subfamily

Included genera.—*Catalanispira* new genus (and type genus, designated here); *Pelecogyra* Ebbestad and Lefebvre, 2015.

Diagnosis.—Sinistral, low trochiform shell with rapid whorl expansion, a deep funnel-like umbilicus, narrow elliptical aperture, and large cap-shaped protoconch.

Remarks.—Catalanispirinae n. subfam. differs from other subfamilies of the Clisospiroidea by its relatively large shell that can reach nearly 30 mm wide, the low trochiform shape, the narrow elliptical aperture, and large cap-shaped protoconch. The upper surface in all included taxa has fine commarginal ornamentation overlying an irregular and uneven, softly plicate shell surface, most strongly developed in *Pelecogyra*. All apomorphies are known in the type species *Catalanispira plattevillensis* n. gen. n. sp., but all are

not preserved in the Estonian species *Catalanispira reinwaldti* or the Tremadocian *Pelecogyra* known from Morocco and France (Ebbestad and Lefebvre, 2015; Ebbestad et al., in press). The latter is distinguished by the relatively large, low trochiform shell (although compressed), the widely expanding last whorl (although the exact nature of the aperture is unknown), and a large protoconch (although its precise shape is not preserved), which suggest a placement within the new subfamily rather than any of the other three existing subfamilies.

The Devonian *Hyperstrophema*, single member of the subfamily Hyperstropheminae, bears some overall morphological resemblance to the Ordovician taxa, but is tiny with a much smaller protoconch, more rounded whorl profile, and strong, regular spiral and commarginal ornamentation.

Genus *Catalanispira* new genus

Type species.—*Catalanispira plattevillensis* n. gen. n. sp., by original designation.

Other species.—*Catalanispira reinwaldti* (Öpik, 1930).

Diagnosis.—Shell low trochiform with 2.5 sinistrally coiled and rapidly expanding whorls; whorl expansion rate (W) ~ 2; whorl profile narrow lenticular with width ~ 1/3 of height; whorls steeply inclined; umbilical area deep, funnel-like. Protoconch large (> 1 mm across), cap-shaped, and with ornamentation (if present) differing from the teleoconch. Base of aperture falcate, projecting anteriorly. Ornamentation of fine sharp growth lines on upper whorl surface and coarser falcate lines on umbilical surface.

Occurrence.—*Catalanispira plattevillensis* n. gen. n. sp. is found in the lower 2 m of the Mifflin Member of the Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2) in northern Illinois, eastern United States. *Catalanispira reinwaldti* is found in the Middle Ordovician Pärtlioru Member of the Kõrgekallas Formation (Darriwilian; Uhaku regional stage), northern Estonia.

Etymology.—Named after Mr. John A. Catalani, Woodridge Grove, Illinois, in recognition of his generous contributions for more than 40 years to paleontology and to professional paleontologists.

Remarks.—*Catalanispira* n. gen. has some resemblance to species of *Scaevogyra* in the low shell and expansion of the whorls, but the latter have a more naticid-shaped shell, flared aperture in some species, and a more rounded outline of the whorl. Forms like *Matherella* and *Matherellina* have a higher spire and a much shallower umbilicus. Low-spined species of *Laeogyra* and *Kobayashiella* have a somewhat similar shell shape and seemingly a deep umbilicus, but the whorls and whorl profile are much more rounded and ornamentation on the upper whorl surface consists of sharply defined commarginal ribs.

Catalanispira plattevillensis new species
 Figures 3–7

Holotype.—PRI 76973 (Fig. 4.1–4.6).

Diagnosis.—A species of *Catalanispira* with steeply inclined whorls. Last whorl with increased rate of translation so that periphery of previous whorl is at or slightly above suture. Apertural plane at an angle of $\sim 63^\circ$ relative to axis of coiling. Size < 15 mm.

Description.—Shell trochiform, slightly wider than high with maximum width 14 mm. Shell consisting of 2.5 sinistrally coiled, rapidly expanding whorls. Rate of translation low with incremental angle of 90° and whorl expansion rate (W) ~ 2 . Whorl profile narrow, symmetrically lenticular, with width $\sim 1/3$ of height. Peripheral margin sharply rounded, representing lowest point on whorl. Upper whorl surface and umbilical surface steeply inclined ($\sim 45^\circ$ relative to axis of coiling), creating deep, open, funnel-like umbilical area. Whorls adpressed, but because they are steeply inclined and lenticular, whorls barely touching along upper third and imbricated roof-like tiles. In some specimens, last whorl not abutting penultimate whorl abaxially, creating small overhang at suture with groove underneath, suggesting slight increase in rate of translation of last whorl. Aperture tangential, with apertural plane at angle of $\sim 63^\circ$ relative to axis of coiling. Shell thin, perhaps a bit thicker on upper surface and at adapical end of whorl. Ornamentation on upper surface consisting of fine, densely spaced, sharp commarginal growth lines curving backward in wide crescent. Secondary ornamental component consisting of irregularly spaced, subdued ridges underlying and paralleling growth lines, giving somewhat plicate appearance. Growth lines on umbilical surface opisthocline with marked falcate shape, densely spaced, standing out as simple, slightly pronounced, rounded lines. Base of aperture with strong anterior projection. Inner margin and apertural lip reflected, slender, and rod-like, extending from deepest part of umbilicus along approximately half the distance of the margin. Protoconch large, cap-shaped, 1.4 mm wide, ~ 0.5 mm high; ornament obscure, but faint lines subparallel to basal margin can be present. Base circular in outline with apex slightly to one side (adaxially), suggesting sinistral coiling. Apical cap separated from teleoconch by sharp boundary accompanied by change in coiling and ornamentation of succeeding shell. Axis of coiling in the two ontogenetic stages does not seem to coincide. Fine growth lines on teleoconch curving adaperturally at angle of $\sim 25\text{--}30^\circ$ relative to plane of apical cap.

Etymology.—The species is named after the Platteville Formation in which it occurs.

Materials.—Besides the holotype, eight specimens are known (PRI 76974–76977, Dixon site 1; ISGS 1017–1020, Dixon site 2), all from the Mifflin Member, Platteville Formation, 2 m above the Pecatonica Member.

Remarks.—*Catalanispira plattevillensis* n. gen. n. sp. has a remarkable shell with its narrow lenticular aperture and deep funnel-like umbilical area, presented in a sinistrally coiled guise. The whorls are barely touching but overlapping in a characteristic tile-like manner (Fig. 3). The deep falcate shape and anterior projection of the base of the aperture (Figs. 4.3, 7.3) create a basal excavation reminiscent of the excavated sinus seen in some pycnomphalines or the euomphalid *Centrifugus* Bronn, 1835 and others, a feature that could provide space for the foot extending from the aperture. Convergent similarities in the anterior projection and excavation of the base, the tangential aperture, and low, trochiform shell afford striking comparisons with species of Silurian pseudophorids, e.g., *Pseudophorus profundus* (Lindström, 1884) from Gotland, Sweden, although that dextral orthostrophic taxon lacks the extreme elongation of the aperture and the funnel-like umbilical area.

The inner lip of the aperture extends deeply into the umbilicus and its margin has a thin, rod-like appearance adapically, and it thins to just the thin shell toward the base of the aperture (Figs. 4.5, 4.6, 7.4, 7.5). It can be seen as a strengthening feature at this section of the lip against the forces exerted by the foot during clamping or interaction with the substratum. The strength of such a foot against the substratum in a modern gastropod with an elongated aperture and a corresponding elongated foot is not great and often correlates with life on soft substrata (McNair et al., 1981).

Runnegar (1981; see also Runnegar and Pojeta, 1985, p. 36) argued that *Scaevogyra* and *Matherella* had lost one gill, because they were quite large, had no sinus or slit, and had in the last whorl a muscle attached to the shell on the part facing outward. By extension, this could apply as well to other sinistral onychochiloids, although Dzik (1983) speculated that they had paired organs. The strongly elongated aperture in *Catalanispira plattevillensis* n. gen. n. sp. clearly supports the notion that only one gill was present.

The protoconch, observed with some details in specimens PRI 76975 and ISGS 1020 (Fig. 5), is low cap-shaped, probably unornamented, and separated by a distinct line from the coiled teleoconch. The term ‘apical cap’ was used by Wären and Gofas (1996) to describe the symmetrical embryonic shell (protoconch 1) of some Recent monoplacophorans, with a width up to 0.25 mm. The apical cap in *Catalanispira plattevillensis* n. gen. n. sp. on the other hand is uncoiled, slightly asymmetrical, and large (1.4 mm wide). The bulbous, slightly coiled embryonic shells of archaeogastropods and Recent vetigastropods reach maxima of 0.8 mm wide (Nützel, 2014).

The sharp boundary and start of well-developed ornamentation clearly demarcate the apical cap as a protoconch, but it is not entirely clear whether the unusually large apical cap represent the embryonic shell or incorporates the larval shell (protoconch 2). Very faint lines on the side near the margin could suggest a degree of ornamentation present at least on parts of the apical cap (Fig. 5.7), which could suggest that this is part of the larval shell. Furthermore, the very apex of the best-preserved protoconch is exfoliated (Fig. 5.6) in an area ~ 350 μm wide. It is conceivable that this patch was

Figure 4. *Catalanispira plattevillensis* n. gen. n. sp., from base of Mifflin Member, Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2), northern Illinois, eastern USA: (1–6) holotype, ISGS PRI 76973, in dorsal (1), lateral (2), ventral (3), apertural (4), and ventral oblique (5) views, and detail of adumbilical part of inner lip (6); (7–9) PRI 76977, in dorsal (7), apertural (8), and dorsal oblique (9) views. Scale bar = 5 mm.

originally occupied by an embryonic shell, and if so, such an arrangement would indicate the presence of both protoconchs 1 and 2. The larval shell in *Catalanispira plattevillensis* n. gen. n. sp. differs from the protoconch of *Mimospira*, which could include a multiwhorled protoconch 2 (but see discussion).

Catalanispira reinwaldti (Öpik, 1930)

Figure 8

- 1930 *Clisospira reinwaldti* Öpik, p. 25, pl. 2, fig. 12.
 1970 *Clisospira reinwaldti*; Rõõmusoks, p. 94 (table 5), 122 (table 7).
 1979 *Laeogyra? reinwaldti*; Wängberg-Eriksson, p. 18, fig. 5i, j. non 2007 *Laeogyra reinwaldti*; Frisk and Ebbestad, p. 88, fig. 3E–H.

Holotype.—TUG 1053-13, only known specimen, an internal mold from the late Middle Ordovician Pärtlioru Member of the Kõrgekallas Formation (Darrivilian; Uhaku regional stage) at a no-longer-existing quarry at the southern lighthouse in Tallinn, Harju County, northern Estonia.

Diagnosis.—A large species of *Catalanispira* n. gen., with lower inclination of the outer whorl and last whorl overlapping the periphery of the previous whorl. Apical angle and rate of translation low; apertural plane inclined $\sim 70^\circ$ relative to the axis of coiling. Upper shell surface uneven with an irregular plicate appearance.

Description.—Shell low, trochiform, rapidly expanding, with 2.5 whorls. Height $\sim 2/3$ of width; shell 28 mm wide. Incremental angle $\sim 110^\circ$. Whorl profile narrowly lenticular,

Figure 5. *Catalanispira plattevillensis* n. gen. n. sp., from base of Mifflin Member, Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2), northern Illinois, eastern USA: (1–7) ISGS 1020, in dorsal (1), lateral oblique (2), and various lateral (3–5) views, and detail of protoconch (6, 7); (8, 9) PRI 76975, in dorsal (8) and lateral (9) views, showing boundary of protoconch (arrow in 8), and shell damage and repair (arrow in 9). See Figure 6.1–6.3 for entire specimen. Scale bars = 1 mm.

with width $\sim 1/4$ of height, steeply inclined upper whorl surface, and umbilical wall ($\sim 42^\circ$ to axis of coiling), giving deep, open, funnel-like umbilicus. Apertural plane at angle of $\sim 70^\circ$ relative to axis of coiling. Periphery lowest point on whorl, evenly but sharply rounded adumbilically. Last whorl slightly overlapping periphery of previous whorl. Shell missing but upper surface with irregularly spaced, low plicate elevations paralleling growth lines, curving backward in wide arch.

Remarks.—This Estonian species is known from a single internal mold, which is much larger than any specimen of *Catalanispira plattevillensis* n. gen. n. sp. The whorl is less inclined than in the type species, and the last whorl slightly overlaps the previous one. In *Catalanispira plattevillensis* n. gen. n. sp., the last whorl instead seems to have an increased rate of translation. The apical angle and rate of

translation in *Catalanispira reinwaldti* are thus lower than in *Catalanispira plattevillensis* n. gen. n. sp. Shell and ornamentation are not preserved in *Catalanispira reinwaldti*, but growth lines are visible as impressions on the upper whorl surface of the mold, showing the same wide curvature as in *Catalanispira plattevillensis*.

Öpik (1930) assigned the species to *Clisospira* Billings, 1865, which is a medium to low-spired sinistral taxon with a distinct peripheral frill and cancellate ornamentation.

Öpik (1930) reported the species from the Kukruse beds (C_{II}) at the southern lighthouse in Tallinn, most likely because he recognized kukersite deposits there, but the beds at this site are of the Kõrgekallas Formation, which there had kukersite deposits in its upper part (personal communication, H. Bauert, 2019). This placement was also given by Rõõmusoks (1970, p. 122) who reported the species from level C_{Ica} .

Figure 6. *Catalanispira plattevilensis* n. gen. n. sp., from base of Mifflin Member, Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2), northern Illinois, eastern USA: (1–3) PRI 76975, in dorsal (1), lateral (2), and oblique (3) views; the shell in (2) is oriented to show the approximate left lateral view of shell in life position; see Figure 5.8 and 5.9 for details of apex and shell repair; (4–8) ISGS 1017, in dorsal (4), ventral oblique (5), dorsal oblique (6), and lateral (7) views; white arrow in (4) points to the halt in growth; shell in (8) oriented to show approximate left lateral view of shell in life position. Scale bar = 5 mm.

Discussion

Protoconch morphology.—Much of the discussion concerning mimiospirid phylogeny centers on the interpretation of protoconch morphology of *Mimospira*. This is a small genus with a shell of up to six whorls. Some species, including the type species *Mimospira helmhackeri* (Perner, 1900) can reach 7–9 mm in height (Knight, 1941; Wängberg-Eriksson, 1979) but most taxa are no more than 1–4 mm. In total, ~20 species

are described and, except for two Silurian occurrences, are Ordovician in age (Peel, 1975, 1986; Wängberg-Eriksson, 1979; Frýda, 1989; Isakar and Peel, 1997; Frýda and Rohr, 1999; Frisk and Ebbestad, 2007; Dzik, 2020).

The protoconch of *Mimospira* seems to consist of an embryonic shell (protoconch 1) and a multiwhorled larval shell (protoconch 2). A two-stage protoconch is found in taxa with planktotrophic development, whereas a one-stage protoconch is found in basal gastropod clades with nonplanktotrophic

Figure 7. *Catalanispira plattevilensis* n. gen. n. sp., from base of Mifflin Member, Platteville Formation (*Diplograptus foliaceus* Biozone, Turinian regional Stage, Sandbian 2), northern Illinois, eastern USA: (1–5) PRI 76974, in dorsal (1), lateral (2), ventral (3), ventral oblique (4), and apertural (5) views; note falcate shape of inner lip; (6–8) ISGS 1019, in dorsal (6), lateral (7), and dorsal oblique (8) views; white arrow in (6) points to the marked halt in growth after approximately one whorl. Scale bar = 5 mm.

development (Geiger et al., 2008; Nützel, 2014). Although size ranges overlap, a small embryonic shell generally indicates planktotrophic development, whereas a larger embryonic shell (0.1–0.8 mm in modern vetigastropods) is found in taxa with

nonplanktotrophic development (Bandel, 1982; Geiger et al., 2008; Frýda, 2012; Nützel, 2014). Nonplanktotrophy could reflect the ancestral condition in gastropods, whereas planktotrophic development might have developed in the late

Figure 8. *Catalanispira reinwaldti* (Öpik, 1930), holotype, TUG 1053-13, from late Middle Ordovician Pärtlioru Member, Kõrgekallas Formation (Darrivilian; Uhaku regional stage), at no-longer-existing quarry at southern lighthouse, Tallinn, Harju County, northern Estonia, in dorsal (1), lateral (2), ventral (3), apertural (4), dorsal oblique (5), ventral oblique (6), apertural oblique (7), lateral (8), and lateral oblique (9) views. Scale bar = 10 mm.

Cambrian–Early Ordovician (Nützel et al., 2006, 2007; Nützel, 2014); Nützel et al. (2006, 2007) applied a method to distinguish between embryonic shells with planktotrophic vs those with nonplanktotrophic development, in which the width 100 μm from the apex was used; a value $< \sim 100 \mu\text{m}$ at this point could indicate planktotrophic development. The transition between protoconchs 1 and 2 is usually clearly marked by change in growth and start of or a change in ornamentation; the transition to the teleoconch, when the larva undergoes metamorphosis, is abrupt (Nützel, 2014). However in fossil material, the boundary between the embryonic shell and the larval shell can be quite difficult to see (Nützel et al., 2007).

Dzik (1983) described the morphology of small specimens of *Mimospira* sp. mainly from internal molds. The single-whorled embryonic shell (protoconch 1) was shown to be 0.4 mm wide, after which there is a clear change in shape and ornamentation. Considerable variation in the number of whorls was described from subsequent whorls in what Dzik (1983) referred

to as juvenile shells. Dzik (1983, p. 235) also stated that the embryonic shell is homostrophic with the teleoconch. It should be mentioned that the protoconch of the Silurian *Mimospira abbea* Peel, 1975 was regarded as heterostrophic (Peel, 1975).

Frýda (1989) closely compared protoconch development in his new species, *Mimospira barrandei* Frýda, 1989, with that of Dzik's (1983) material. He showed that the transition to an ornamented teleoconch appeared after 1.5 whorls in *Mimospira barrandei* at a width ~ 0.4 mm, and after slightly less than 2 whorls in *Mimospira helmackeri* but at greater width. Isakar and Peel (1997) described a smooth, bulbous protoconch in *Mimospira puhmuense* Isakar and Peel, 1997 consisting of 1.5 whorls at a width of 0.4 mm, before the ensuing ornamented teleoconch reaching a height ~ 2 mm.

A two-staged protoconch in *Mimospira* (embryonic + larval shell) as described by Dzik (1983) would imply that the initial embryonic shell (0.4 mm wide) is followed by a multi-whorled larval shell of < 1 mm diameter. Larger specimens

that could show the transition to a teleoconch are not preserved in Dzik's (1983) material; however, it is possible to interpret the abrupt change in shape and ornamentation directly following the embryonic shell shown in a few well-preserved specimens (Dzik, 1983, fig. 3) as transitions to the teleoconch, in which case all of the small multiwhorled shells would be juvenile teleoconchs and not larval shells. By extension, the protoconchs discussed by Frýda (1989) and Isakar and Peel (1997) could also represent embryonic shells only. However in these examples, the transition to a teleoconch, as marked by the abrupt change in ornamentation, seems to follow after slightly more than one whorl. Therefore, because the embryonic shell (protoconch 1) consists of approximately one whorl (Nützel, 2014), it would seem that in these examples the embryonic shell is followed by an unornamented protoconch 2 before the ornamented teleoconch. However, an embryonic shell per se has not been clearly identified in the two last examples and, to paraphrase Nützel et al. (2007), whether these protoconchs represent larval shells (protoconch 2) in which the embryonic shells (protoconch 1) are obscured or just a large protoconch 1, remains ambiguous.

Protoconchs in other mimospirids are not well known. The protoconch (internal mold) of the specimen identified as *Clisospira* sp. by Dzik (2020) is just over one whorl with a tapered apex, similar in shape and size to the illustrated tapered apex in the specimen attributed to *Laeogyra reinwaldti* by Frisk and Ebbestad (2007, now assigned to *Laeogyra* sp.). The specimen is ~1.5 mm in diameter, consisting of 1.5 whorls, with the width of the seemingly smooth apex 0.26 mm at the transition to an ornamented teleoconch. Internal molds of *L. volhynica* Hynda, 1986 and *L. alta* Hynda, 1986 are each ~1 mm in diameter. The former shows a bulbous initial part, slightly less than 0.2 mm in diameter, followed by a smooth first whorl and then half a whorl with what appears to be impressions of ornamentation. The latter has more whorls, but the bulbous apex is quite similar. Possible impressions of ornamentation appear after approximately two whorls. In all four cases, the width at ~100 µm length from the apex is > 180 µm, indicating that only protoconch 1 is present if using the proxy of Nützel et al. (2006, 2007).

It is unclear whether the unusually large protoconch of *Catalanispira* n. gen. represents a larval shell (protoconch 2) or not, and it is therefore uncertain if it had a nonplanktotrophic or planktotrophic development. The uncoiled, slightly asymmetrical protoconch differs from those known in other mimospirids, regardless of its interpretation, which illustrates the disparity in protoconch morphologies within mimospirids.

Mode of life.—An elongated aperture suggests that its axis was subparallel to the long axis of the foot (Linsley, 1977; McNair et al., 1981). Alignment of *Catalanispira* n. gen. in this way and the relatively high angle of inclination of the apertural plane would place the spire slightly inclined to the right and offset posteriorly. Figure 6.2 and 6.8 show the shell in approximately this position. The aperture in *Catalanispira* n. gen. is described as tangential. None of the available specimens preserve the entire apertural margin of the outer lip, but its growing margin extends quite far adaperturnally relative to the inner lip. The arrows in Figure 4.1 and 4.3 show the

approximate point where the contact breakage between the whorl and adaxial margin of the outer lip is seen in the holotype. The shape of the outer lip is also evident from growth lines preserved on the upper surface. With the apertural plane parallel to the substratum as outlined above, the position of the shell resembles that of some Silurian pseudophorids, a group with prominently tangential apertures (Wagner, 2002). However, owing to the very deep, funnel-like umbilical area, the apertural plane would not be entirely parallel to the surface, but would extend obliquely into the umbilicus. In shape and function, it would appear similar to the umbilical morphology seen in the mostly sessile, filter-feeding caenogastropods of the family Calyptraeidae (Lamarck, 1809), among which the umbilical resemblance of the so-called Chinese hat, *Calyptraea chinensis* (Linnaeus, 1758), is a good analogue. Only a few genera in the family have expressed coiling (Collin and Cipriani, 2003).

Injuries and disturbances to the shell.—Five specimens of *Catalanispira plattevillensis* n. gen. n. sp. show irregularities in growth on the upper surface of the first whorl, and one shows disturbances in growth on the umbilical side. After one whorl in PRI 76977, at a width of 4.6 mm, the apertural outline is marked by a sharp growth line, suggesting a halt in growth (Fig. 4.7). This is also the case in specimens ISGS 1017 and 1019, in which a similar but less pronounced growth halt is evidenced by a more strongly outlined growth line at widths of 5.3 mm and 6.3 mm, respectively (Figs. 6.4, 7.6). In the same position in PRI 76975, at a width of 4.5 mm, the aperture has been broken along nearly the entire margin, creating a large irregular scar stretching subparallel to the apertural edge from close to the upper suture to the periphery (Figs. 5.8, 5.9, 6.1, 6.3). The injury is obscured by the succeeding whorl but probably continues on the umbilical side. Close to the periphery, a crack extends a short distance backward from the edge of the injury. The new shell extends from the fractured edge and its growth is a bit irregular in the area just adaperturnal to the scar margin, but normal growth is restored shortly thereafter. In the third specimen (PRI 76974), growth is disturbed after half a whorl, as seen by a thickened and irregular section that is only subparallel to the growing edge (Fig. 7.1).

Irregular growth is seen on the umbilical side of the holotype of *Catalanispira plattevillensis* n. gen. n. sp. (PRI 76973; Fig. 4.3, 4.6). The falcate apertural margin at slightly more than half a whorl back is strongly outlined by a thickened growth line, from which a spiral line continues adaperturnally on the surface close to the periphery. It gives the impression of an umbilical carina, but likely results from an irregularity in the growth perhaps from an irritated or injured mantle.

Changes or halts of growth in gastropod shells are sometimes triggered by unfavorable or stressful conditions, but these would introduce a random distribution of such disturbances. The halt in growth observed in four specimens of *Catalanispira* n. gen. appears at approximately the same size in each individual and could therefore be deterministic. One possibility is that they could mark the transition from a vagile to a sessile lifestyle. Seasonal changes in growth can be excluded,

considering the equatorial position of *Laurentia* in the Katian (Torsvik and Cocks, 2017). The more obvious shell damage and subsequent repair, coinciding with the halt in growth in specimen PRI 76975, could be attributed to failed predation or abiotic chipping of the shell (e.g., Ebbestad et al., 2009; Peel, 2015, and references therein).

Conclusion

Mimospirids are an unusual group of mollusks, not only because of their sinistrally coiled shells. The conch morphology, although not well known in many taxa, differs in many respects from that of regular orthostrophic gastropod morphologies by the shapes of the whorl and aperture, the deep umbilicus, and coiling properties. The possible presence of a two-staged protoconch is also highly unusual because this feature is prevalent in advanced gastropods since the mid-Paleozoic (Frýda, 2012; Nützel, 2014). However, the evidence for mimospirids having a protoconch 2 relies mostly on a few findings in *Mimospira*, and it may be possible to interpret these differently. An abrupt change in morphology and ornamentation following the embryonic shell seen in a few well-preserved specimens of *Mimospira* could mark the transition to the teleoconch, in which case only a protoconch 1 is present. Supportive data from a few other mimospirids attributed to *Clisospira* and *Laeogyra*, could suggest that they also had only a protoconch 1, but more research is needed.

The new taxon *Catalanispira* n. gen. from the Ordovician of Estonia and USA is a large mimospirid mollusk. It is placed in *Catalanispirinae* n. subfam. of the *Onychochilidae* along with the Lower Ordovician *Pelecogyra* from Morocco and France, distinguished by a low trochiform and widely expanding shell, an elongated aperture, a deep funnel-like umbilicus, and an extremely large cap-shaped protoconch.

The protoconch of *Catalanispira* n. gen. is slightly asymmetrical and seemingly homeostrophic with the teleoconch. In *Mimospira*, both homeostrophic and heterostrophic protoconchs have been described (Peel, 1975; Dzik, 1983; Frýda, 1989). Although well-preserved, it is unclear whether the protoconch in *Catalanispira* n. gen. represents protoconch 2 or not, but it emphasizes the disparity in protoconch morphologies within the mimospirids.

An elongated aperture suggests that *Catalanispira* n. gen. had only one gill, and that the aperture was oriented with the long axis subparallel to the axis of the foot. The inclination of the apertural plane further suggests that the spire was tilted slightly backward to the right.

Dextral hyperstrophy (dextrally arranged organs, sinistrally coiled shell) is found in a number of lower Paleozoic gastropods, but it has been argued that the sinistral asymmetry already in the embryonic shell of *Mimospira* demonstrates sinistral orthostrophy among mimospirids (Dzik, 1983, 1999). Lack of conclusive evidence, such as an operculum, and the general problem of establishing hyperstrophy vs sinistral orthostrophy based on the shell alone, also preclude firm conclusions about the nature of shell coiling in mimospirids. Furthermore, the modified concept of a presumed untorted class *Paragastropoda*, now only including the mimospirids, has undermined the validity of that concept (Frýda et al., 2008; Frýda, 2012).

Nützel (2014) expected higher disparity and different forms and clades among early gastropods, and mimospirids could very well represent part of a mainly late Cambrian and Ordovician clade of sinistrally coiled mollusks that later went extinct. Whether they are sinistrally coiled gastropods, either hyperstrophic or orthostrophic, or a unique sinistrally coiled gastropod-like mollusk remains unsettled.

Acknowledgments

Four specimens of *Catalanispira* n. gen. were generously provided by J.A. Catalani of Woodridge Grove, Illinois. Many thanks to H. Bauert, Tallinn, Estonia for information on the original collection site of Öpik (1930). J.S. Peel, Uppsala, Sweden is thanked for providing insightful comments and discussion on an earlier draft. This paper is a contribution to Project IGCP 653, ‘The onset of the Great Ordovician Biodiversity Event.’ Comments and suggestions from D.M. Rohr, Alpine, Texas and J. Frýda, Prague, are gratefully acknowledged.
