Abstract

Clostridioides difficile infection (CDI) research relies upon accurate identification of cases when using electronic health record (EHR) data. We developed and validated a multi-component algorithm to identify hospital-associated CDI using EHR data and determined that the tandem of CDI-specific treatment and laboratory testing has 97% accuracy in identifying HA-CDI cases.

(Received 6 March 2024; accepted 25 June 2024)

Background

Healthcare-associated *Clostridioides difficile* infection (HA-CDI) represents about two-thirds of CDI cases in the United States.^{1,2} Retrospective epidemiologic studies have focused on identifying risk factors, evaluating diagnosis and treatment appropriateness, and measuring attributable outcomes for HA-CDI.^{3,4} However, the validity of this research relies on accurate identification of HA-CDI cases, and previous studies of other infections have demonstrated that reliance on administrative or laboratory data may lead to misclassification.^{5,6}

We developed and validated a CDI case definition to accurately detect CDI cases using antibiotic treatment, laboratory test, and diagnosis code data in the electronic health record (EHR) to specifically be used for retrospective research. We hypothesized that a multi-component case definition would more accurately detect patients with CDI compared to any single-component case definition.

Method

Study design and data source

This validation study was conducted including all Oregon Health & Science University (OHSU) inpatient hospital encounters between January 2018 and March 2020. OHSU is a 576-bed academic, quaternary-care hospital in Portland, Oregon. We excluded patients under age 18, those with known recurrent or

community-acquired CDI, and those with hospital stays of less than four calendar days. Eligible subjects were sampled for chart review as described below and in Supplemental Figure 1. This project was approved by OHSU's institutional review board.

Case definition algorithm to identify incident hospital-associated CDI

EHR data were collected from our institution's previously validated research data repository.⁷ To identify putative cases of incident, non-recurrent HA-CDI, we combined medication, diagnosis code, and laboratory testing data (Box 1). We defined hospital-associated CDI as incident CDI when the onset date, defined as the date of first anti-*C. difficile* antibiotic administration or *C. difficile* positive stool specimen, whichever occurred first, fell on hospital day 4 or later. We defined CDI as non-recurrent if no prior CDI events were identified at our institution in the 8 weeks before the index CDI diagnosis applying the same diagnostic criteria.

Collection of gold-standard incident HA-CDI data

We randomly selected 80 algorithm-identified HA-CDI cases and 80 non-CDI cases for chart review to identify the gold-standard "true" case status. We determined *a priori* that this sample size would be sufficient to achieve 94% power to discern cases from non-cases.⁸ We (MJR, KLL, MRL, KR) manually reviewed each encounter medical record (Epic EHR system). To be ruled a true case of HA-CDI and establish our gold standard, there must have been documentation of, on hospital day 4 or later, at least three loose/liquid/unformed stools with no alternative explanation documented for diarrhea symptoms, initiation of CDI-specific antibiotic treatment, and any positive laboratory test (*C. difficile*

Box 1. Case definition for incident hospital-associated <i>C. difficile</i> infection cases	
HO-CDI Definition	Value
Anti-CDI antibiotic therapy initiated on hospital day four or later	Oral/rectal Vancomycin Metronidazole Fidaxomicin
AND at least one of the following:	
Any positive laboratory test; sample collected on hospital day four or later	PCR, Stool toxin A, Toxin B
OR	
ICD-10-CM code present	ICD-10-CM (A04.72: Enterocolitis due to <i>Clostridioides difficile</i> , not specified as recurrent)
Incident Case Definition	
Non-recurrent – no known CDI in the previous 8 weeks	

toxin or PCR if toxin test indeterminate) for *C. difficile* or *C. difficile*-specific diagnosis code. We flagged the record for further review by an infectious disease physician (LCS) or pharmacist (KR) if the initial reviewer was unable to reach a CDI ruling. We utilized REDCap to collect study data.

Data analysis

We calculated our case algorithm's sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and overall percent accuracy (ie, percent of cases/non-cases correctly identified) with 95% confidence intervals (CI) for each.⁸ Chart review assessment was considered the gold standard and case identification based on electronic data were considered "test" data. We also examined the diagnostic performance of individual algorithm components (eg, laboratory test only, diagnosis code only, oral vancomycin only) and various modifications to the algorithm (Box 1). Our power calculation was performed using Stata (version 16, StataCorp., College Station, TX) and all other analysis using SAS (v9.4, SAS Corporation, Cary, NC).

Results

Of the 103,275 inpatient encounters evaluated, 50,394 (49%) were eligible for inclusion. Overall, 5,039 (10%) of included encounters involved CDI treatment (metronidazole, oral vancomycin, or fidaxomicin), with 710 (14.1%) receiving oral vancomycin or fidaxomicin. A positive test for *C. difficile* was identified in 396 encounters (0.8%), and 487 (1%) had an ICD-10 code for non-recurrent CDI. Per our case definition (Box 1), we identified 190 putative cases of incident, HA-CDI. Among these, 157 (83%) encounters had all three components of our case definition (anti-CDI therapy, positive laboratory test, and ICD-10 code). Of the 80 algorithm-identified HA-CDI cases that we sampled for review, 66 (83%) had all three criteria, while 9 (11%) had a positive laboratory test and no ICD-10 code, and 5 (6%) had an ICD-10 code and no positive laboratory test.

Among our chart review sample, our algorithm identified HA-CDI cases with 94% accuracy (95% CI: 88%–97%). We achieved 100% sensitivity (94%–100%), 89% specificity (81%–95%), 88% PPV (78%–94%), and 100% NPV (95%–100%). Performance of the individual algorithm components is summarized in Table 1. Adapting the initial algorithm to require a positive laboratory test

Table 1. Diagnostic performance of our CDI algorithm and comparison of individual algorithm components among 80 algorithm-identified HA-CDI cases and 80 non-cases

Case definition criteria	Diagnostic performance measure, % (95% CI)	
Initial study algorithm: ICD-10-CM code A04.72 OR positive <i>C. difficile</i> laboratory test AND CDI-specific antibiotic (metronidazole, oral vancomycin, fidaxomicin)	Sensitivity	100 (94–100)
	Specificity	89 (81–95)
	PPV	88 (78–94)
	NPV	100 (95–100)
	Accuracy	94 (88–97)
Revised study algorithm: Positive <i>C. difficile</i> laboratory test AND CDI-specific antibiotic	Sensitivity	100 (94–100)
	Specificity	94 (87–98)
	PPV	93 (85–98)
	NPV	100 (96–100)
	Accuracy	97 (93–99)
Code required: ICD-10-CM code A04.72 AND CDI-specific antibiotic	Sensitivity	93 (84–98)
	Specificity	94 (87–98)
	PPV	93 (84–98)
	NPV	94 (87–98)
	Accuracy	94 (88–97)
Any CDI drug only: CDI-specific antibiotic (metronidazole, oral vancomycin, fidaxomicin)	Sensitivity	74 (64–83)
	Specificity	73 (63–82)
	PPV	74 (64–83)
	NPV	100 (95–100)
	Accuracy	85 (78–90)
Oral vancomycin only	Sensitivity	100 (94–100)
	Specificity	79 (69–87)
	PPV	79 (68–87)
	NPV	100 (94–100)
	Accuracy	88 (82–93)
Positive <i>C. difficile</i> laboratory test only	Sensitivity	100 (94–100)
	Specificity	83 (74–90)
	PPV	82 (72–90)
	NPV	100 (95–100)
	Accuracy	91 (85–95)

Abbreviations: CI, confidence interval; PPV, positive predictive value; NPV, negative predictive value.

(as opposed to an optional positive test if an ICD-10 code for CDI was included) improved diagnostic performance across all measures by avoiding 5 false positives, compared to the original algorithm, improving specificity to 94% (87%–98%), PPV to 93% (84%–98%), and overall accuracy to 97% (93%–99%).

Discussion

Our study suggests that the best strategy to identify inpatient HA-CDI cases relies on a combination of drug administration and laboratory testing test; use of ICD-10 code data does not improve

case identification. Requiring a positive *C. difficile* laboratory test further improved the diagnostic accuracy by avoiding 5 false positives, and use of multiple components performed better than any individual component.

Our study advances the methodological foundation for future retrospective epidemiologic studies of HA-CDI by providing a validated, accurate method for case identification. Much of the literature to date examines the utility of using a single component to detect cases. For example, Litvin et al. observed a “pseudo-outbreak” of CDI using a laboratory-test-only-based definition, which was, in reality, due to a faulty assay lot leading to a perceived 32% facilitywide increase in CDI incidence.⁹ Pfister et al. reported that the ICD-10-CM code for non-recurrent CDI had 85% sensitivity and 80% PPV when applied to a provincewide (Alberta, CA) discharge database.¹⁰ These studies identify important pitfalls of single-component case detection, thus motivating our study.

The primary limitation to this study is the assessment of the gold-standard HA-CDI diagnosis, which relies on EHR documentation and may not align with a prospective case evaluation, had that been feasible. Further assessment at additional facilities is necessary to determine if these results are generalizable, given differences in patient acuity, CDI incidence, testing, and antibiotic utilization. Additionally, while we calculated power/sample size *a priori*, it is possible that we underestimated our denominator for sensitivity and NPV calculations, though this would not affect our specificity and PPV calculations. Finally, we are unable to elucidate if an individual had CDI at another institution. Thus, we could be misclassifying recurrent CDI as initial episodes.

Our study has important implications. Our CDI case definition algorithm can be applied as a gold standard to readily available EHR information to accurately detect HA-CDI cases. Accurate retrospective identification of CDI cases is crucial for research as misclassification could lead to biased estimates of risk. Our algorithm detected HA-CDI cases with perfect sensitivity and high overall accuracy. Requiring a positive laboratory test further improved our algorithm’s diagnostic accuracy. We recommend considering both a CDI-specific medication and a positive laboratory test as the new standard research definition when classifying HA-CDI cases from EHR data.
