## Abstract

The domestication of rice increases the divergence between cultivated rice and its wild progenitor because of artificial selection. However, it remains unknown whether highly diverged loci in rice can be explained by neutral demographic scenarios alone. In this study, we genotyped 45 InDels (insertion/deletion) in two subspecies of Asian cultivated rice (*Oryza sativa* ssp. *japonica* and *Oryza sativa* ssp. *indica*) and their wild progenitor (*O. rufipogon*/*O. nivara*). Among them, 17 loci are highly diverged ( $F_{ST} > 0.4$ ) between rice cultivars and their ancestor. We performed coalescent-based simulations on neutral demographic scenarios and found that neutral demography alone could explain the polymorphic profiles on those highly diverged loci between cultivated and wild rice. Therefore, more signatures of selection should be considered when detecting artificial selection in rice.

## Introduction

Artificial selection is a selection process by which human instead of nature select animals or plants with desirable traits to reproduce. After thousands of years, domesticated animals and plants often have distinct characteristics comparing with their wild progenitors. To study the molecular mechanism of artificial selection, it is important to map genes affected by artificial selection during domestication because these genes are commonly related to economic traits or biological processes associated with development and reproduction (Gepts, 2014). To date, there are different methods and software available to detect artificial selection (Li and Stephan, 2006; Sabeti *et al.*, 2006; Li 2011; Lin *et al.*, 2011; Fu and Akey, 2013; Waldmann *et al.*, 2020). When artificial selection occurs in one of populations, it increases the fixation index ( $F_{ST}$ ) on the selected locus.  $F_{ST}$  is a measurement of population differentiation (Hartl and Clark, 1997), and a locus with high  $F_{ST}$  indicates that two populations are highly diverged on the locus. Therefore, high  $F_{ST}$  has been frequently used as one of the signatures of selection in rice and many other species (Gao, 2004; Yu *et al.*, 2008; Fabian *et al.*, 2012; Huang *et al.*, 2012; Daub *et al.*, 2013; Shen *et al.*, 2014; Kumagai *et al.*, 2016; Islam *et al.*, 2018; Cheng *et al.*, 2019).

It has been well-known that demographic factors, such as population structure and varying population size, may generate selection-like signatures in the genetic variation of domesticated animals or plants (Catriiona and Emma, 2006; Li and Stephan, 2006). Thus, it may hinder the efforts to detect artificial selection. To examine the confounding effects of demography, we investigated whether the polymorphism on highly diverged loci (i.e. high  $F_{ST}$  loci) could be accounted by neutral demographic scenarios alone, without invoking the hypothesis of artificial selection.

We used Asian rice to examine the confounding effects of demography, including population structure and varying population size. Asian rice (*Oryza sativa* L.) has two subspecies, *indica* and *japonica*, and it domesticated from its wild rice ancestor *O. rufipogon* Griff. (He *et al.*, 2011; House *et al.*, 2014; Zhang *et al.*, 2016). An entangled history of rice domestication has been revealed (Huang *et al.*, 2012). As common variants in rice (Shen *et al.*, 2004), InDels (insertion/deletion) may be good neutral markers and are easy to be genotyped. Polymorphisms of InDels have gained long-term interests in the rice research community (Shen *et al.*, 2004; Liu *et al.*, 2015a; Lu *et al.*, 2015; Moonsap *et al.*, 2019), and these markers were used to conduct QTL mapping (Kim *et al.*, 2016) and study genetic differentiation in rice (Liu *et al.*, 2012; Sahu *et al.*, 2017). In this study, we selected the highly diverged InDels between the rice cultivars (*japonica* or *indica*) and their wild ancestors, *O. rufipogon* and *O. nivara* (also recognized as the annual type of *O. rufipogon*) (Yamanaka *et al.*, 2003; Zheng and Ge 2010; Liu *et al.*, 2015b) and genotyped these loci in 172 accessions of rice collected through the East, South and Southeast Asia. Then we conducted large-scale coalescent-based simulations on neutral demographic scenarios to examine whether the polymorphic profiles on the highly diverged loci can be explained

by demography alone. This study would shed lights on how genes affected by artificial selection could be detected in Asian cultivated rice and other domesticated animals and plants.

## Materials and methods

### Sampling and InDels genotyping

In this study, total 172 accessions of *japonica* ( $n = 63$ ), *indica* ( $n = 66$ ), *O. rufipogon* ( $n = 25$ ) and *O. nivara* ( $n = 18$ ) were collected through the East, South and Southeast Asia (Table S1). These samples were provided by the International Rice Research Institute, the Shanghai Center for Agricultural Biological Genetics, Zhejiang University and Yunnan Agricultural University, respectively, and most of their genomes have not been sequenced. The 45 InDels were genotyped in the collected accessions (Table S2). Those InDels were initially discovered by comparing the genomic sequences of *indica* (93–11) and *japonica* rice (Nipponbare) (Shen *et al.*, 2004; Lu *et al.*, 2009). They are randomly distributed along the rice genome.

Genomic DNA extraction and InDels genotyping was conducted according to our previous published methods (Lu *et al.*, 2009). Seedlings of rice samples were germinated in an incubator at 37 °C and then transferred into a glasshouse at around 25 °C. About 0.5 g of fresh leaf samples were collected from seedlings at about the 3–4-leaf stage and then placed in a plastic bag containing silica gel for fast drying. Genomic DNA was extracted using the hot CTAB procedure (Murray and Thompson, 1980). PCR analysis and electrophoresis were performed. The primers for the 45 InDels were obtained by the previous research (Shen *et al.*, 2004) and listed in Supplemental Table S3. PCR products were resolved on a 4% denaturing polyacrylamide gel. After electrophoresis, bands were revealed using the silver-staining procedure. The electrophoretic banding patterns were used for genotyping and subsequent calculation of allele frequency.

Heterozygosity and  $F_{ST}$  calculation follows the textbook (Hartl and Clark, 1997). Heterozygosity of wild rice, *japonica* and *indica* at each InDel was calculated from allele frequency. To calculate

$F_{ST}$ , we used the following formula:  $F_{ST} = \frac{H_T - H_S}{H_T}$ , where  $H_T$  is expected heterozygosity for total population and  $H_S$  is average expected heterozygosity in subpopulations.

### Model selection and simulated neutral demographic scenarios

Four demographic models were considered here (Fig. 1). Two of them represent the single evolutionary origin of rice, and the other two models stand for the multiple origins. Here, the single origin means that *O. sativa* was domesticated once and diverged to *japonica* and *indica* (Sang and Ge, 2007; Gross and Zhao, 2014). The multiple origins indicate that *japonica* and *indica* have independent origins from distinct wild rice subpopulations (Oka, 1988).

By using a software *ms* (Hudson, 2002) we simulated the neutral data under the demographic scenarios. The parameters of the four demographic models were obtained from the previous study (Molina *et al.*, 2011). Thus, to simulate the data, the *ms* command lines are as following:

Model I (single origin, *japonica* domesticated first):

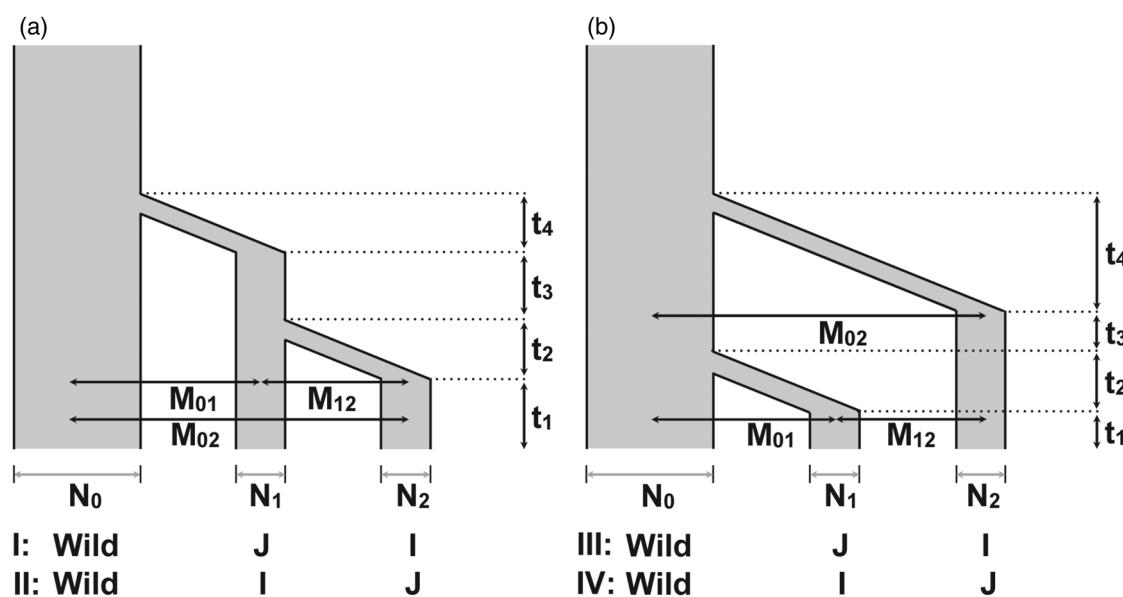

```
ms 344 100000000 -s 1 -I 3 86 126 132 -n 2 0.07 -en 1 2 0.01
-ej 1 2 1 -n 3 0.07 -en 0 3 0.01 -ej 0.07 3 2 -m 1 2 2.01 -m
1 3 5.07 -m 2 3 2.35
```

Model II (single origin, *indica* domesticated first):

```
ms 344 100000000 -s 1 -I 3 86 126 132 -n 2 0.07 -en 0 2 0.01
-ej 0.04 2 3 -n 3 0.09 -en 1 3 0.01 -ej 1 3 1 -m 1 2 1.57 -m
1 3 3.84 -m 2 3 2.16
```

Model III (multiple origins, *japonica* domesticated first):

```
ms 344 100000000 -s 1 -I 3 86 126 132 -n 2 0.08 -en 1 2 0.01
-ej 1.01 2 1 -n 3 0.1 -en 0 3 0.01 -ej 0 3 1 -m 1 2 1.85 -m
1 3 4.02 -m 2 3 1.37
```

**Figure 1.** Four demographic scenarios of rice populations considered in this study. (a) The single origin of rice: the model I: *japonica* rice was first domesticated; the model II: *indica* rice was first domesticated. (b) The two origins of rice: the model III: *japonica* rice was first domesticated; the model IV: *indica* rice was first domesticated.

Model IV (multiple origins, *indica* domesticated first):

```
ms 344 100000000 -s 1 -I 3 86 126 132 -n 2 0.1
-en 0 2 0.01 -ej 0.01 2 1 -n 3 0.11 -en 1 3 0.01 -ej
1.01 3 1 -m 1 2 1.41 -m 1 3 3.51 -m 2 3 1.59
```

#### Neutrality test

The null hypothesis is one of the neutral demographic scenarios described above. The alternative hypothesis is that, a locus evolved neutrally in the progenitor population, but was subject to artificial selection in one of the cultivated rice populations. As expected, artificial selection could cause a high  $F_{ST}$  between progenitor-*japonica*, progenitor-*indica* or *japonica-indica*. We pooled simulated results as a sample by rejection-sampling algorithm (Tavare *et al.*, 1997) that has been commonly used to compare simulated and observed data (Li *et al.*, 2016). The neutrality test was conducted as  $P(f_j > f_{j,obs} | |f_p - f_{p,obs}| < \varepsilon)$  and  $P(f_i > f_{i,obs} | |f_p - f_{p,obs}| < \varepsilon)$ , where  $f_p$ ,  $f_j$  and  $f_i$  are the allele frequency of mutant in the progenitor, *japonica* and *indica* population, and  $\varepsilon$  is a fixed tolerance.

When  $\varepsilon$  is very small, the computational load would be very large to estimate the probability, whereas the precision of the probability will be poor when  $\varepsilon$  is large. Our experience suggests that  $\varepsilon = 0.02$  works well.

## Results

In this study, we surveyed the genetic diversity of 129 accessions of Asian cultivated rice (*O. sativa* ssp. *japonica* and *O. sativa* ssp. *indica*) and 43 accessions of wild rice (*O. rufipogon* and *O. nivara*).  $F_{ST}$  at 45 InDels loci was calculated among wild rice and Asian cultivated rice (Table S2).  $F_{ST}$  was widely used to measure the level of population differentiation and detect artificial selection in rice populations. Twelve of the 45 loci between wild rice and *japonica* (Table 1), 5 of the 45 loci between wild rice and *indica* (Table 2), and 35 of the 45 loci between *japonica* and *indica* showed a  $F_{ST}$  value greater than 0.4. We defined highly diverged locus between *japonica* (or *indica*) and wild rice with  $F_{ST} > 0.4$  as previous study (He *et al.*, 2011). So 17 loci are highly diverged between *japonica* (or *indica*) and wild rice. These loci are R1M7, R1M37, R1M47, R2M10, R2M24, R2M26, R2M50, M3M10, R3M23, R3M30, R4M17, R4M43, R4M50, R6M44, R7M37, R8M23 and R9M42. Because neutral demographic scenarios could affect  $F_{ST}$ , we tested whether the polymorphism pattern at these highly diverged loci can be explained by neutral demographic scenarios alone.

The rice domestication process has been studied well (Gross and Zhao, 2014; Choi *et al.*, 2017; Fornasiero *et al.*, 2022; Izawa, 2022; Shang *et al.*, 2022). It was suggested that the first domestication of Asian cultivated rice occurred in the Yangtze River basin at about 9000 years ago (Fornasiero *et al.*, 2022), but the two subspecies (*japonica* and *indica*) originated independently (Choi *et al.*, 2017), indicating that different loci may have different evolutionary histories due to migration and introgression. Therefore, we simulated four different neutral demographic scenarios (the models I, II, III and IV) of the single and the multiple origins (Fig. 1), which represent the possible neutral evolutionary histories of genes in two cultivated rice subspecies.

We then compared the simulated and observed data using the proposed neutrality test (see Materials and Methods). At 17 highly diverged loci in the four models, we only observed

<sup>a</sup>Model I (single origin, *japonica* domesticated first).

<sup>b</sup>Model II (single origin, *indica* domesticated first).

<sup>c</sup>Model III (multiple origins, *japonica* domesticated first).

<sup>d</sup>Model IV (multiple origins, *indica* domesticated first).

**Table 2.** Probability value for the test of neutrality in the five highly diverged InDel loci between *indica* and wild rice

Locus	<i>O. sativa</i> ssp. <i>indica</i>				$F_{ST}$ ( <i>indica</i> – wild rice)
	pI <sup>a</sup>	pII <sup>b</sup>	pIII <sup>c</sup>	pIV <sup>d</sup>	
R1M37	0.860	0.244	0.655	0.312	0.601
R1M47	0.907	0.265	0.664	0.376	0.468
R2M26	0.736	0.244	0.698	0.258	0.572
R4M17	0.786	0.298	0.691	0.288	0.460
R7M37	0.894	0.289	0.646	0.348	0.446

<sup>a</sup>Model I (single origin, *japonica* domesticated first).

<sup>b</sup>Model II (single origin, *indica* domesticated first).

<sup>c</sup>Model III (multiple origins, *japonica* domesticated first).

<sup>d</sup>Model IV (multiple origins, *indica* domesticated first).

R6M44 in the model I (single origin, *japonica* being domesticated first) with a marginally significant difference ( $p = 0.042$ ) (Tables 1 and 2). The value becomes insignificantly different when the multiple testing is considered. Other  $p$  values are between 0.101 and 1.000. Therefore, the high  $F_{ST}$  at 17 loci may have resulted from demography other than selection during *japonica* and *indica* domestication.

## Discussion

In this study, we genotyped 45 InDels in the privately collected 172 accessions and identified 17 highly diverged InDels between the rice cultivars and their wild ancestors. Large-scale coalescent-based simulations were conducted on four neutral demographic scenarios to test the neutral evolutionary hypothesis of the 17 InDels. The results of neutrality test suggested that demography alone could explain the polymorphic profiles on the highly diverged InDels, irrespective of which domestication hypothesis

was used and which subspecies was first domesticated. Therefore,  $F_{ST}$  is informative for detecting artificial selection in rice, but high  $F_{ST}$  should not be used as conclusive evidence that candidate loci are affected by artificial selection.

To examine these 17 highly diverged loci, the new statistical test was developed. It has a number of advantages. First, the test was conducted conditional on a mutation, thus evolutionary rate heterogeneity in the rice genome (Zhao *et al.*, 2018) does not affect our analyses. Second, the test can be used to analyse a single-point mutation because we did not limit the mutation type as InDels (Yu *et al.*, 2022). Third, the test is based on a single locus assuming no recombination occurred within the locus (Yang *et al.*, 2018). Therefore, the test is ready to be applied to other sexual and asexual species.

Though demography alone could explain the polymorphic profiles on the 17 loci with high  $F_{ST}$ , our results do not indicate that there is no artificial selection during the domestication of rice. The number of loci examined in this study is small, comparing with those in genome-wide surveys. Our results indicate that it is extremely important to consider the demography as a confounding factor when detecting artificial selection in rice (Gao and Innan, 2008; He *et al.*, 2011; Molina *et al.*, 2011). When genome-wide scans are conducted for searching the signal of artificial selection, the number of windows examined increases and it is very likely to observe a number of loci with high  $F_{ST}$  due to random demographic effects, such as demography.

Because the detection of selection may be hindered by the demographic effects, it is further suggested that the combination with different signatures of selection (Lin *et al.*, 2011; Horscroft *et al.*, 2019) could be considered when detecting artificial selection. Moreover, the confounding effects of demography can be addressed by controlling its false-positive rate, which is generally composed by two-step analysis (Li and Stephan, 2006; Koropoulis *et al.*, 2020). Genome-wide DNA polymorphism is used to infer the demography (Speidel *et al.*, 2019; Hu *et al.*, 2023) and the detection of positive selection is followed conditional on the inferred demography. The alternative approaches could be to use neutrality tests that are insensitive to demographic events (Li, 2011; Hunter-Zinck and Clark, 2015). Overall, our results suggest that it should be more cautious about the explanation of highly diverged loci when studying domestication of *indica* and *japonica* rice varieties.
